12 ABSTRACT

13 We report on a first-principles numerical and theoretical study of plasma dynamo in a fully kinetic
14 framework. By applying an external mechanical force to an initially unmagnetized plasma, we develop
15 a self-consistent treatment of the generation of “seed” magnetic fields, the formation of turbulence,
16 and the inductive amplification of fields by the fluctuation dynamo. Driven large-scale motions in
17 an unmagnetized, weakly collisional plasma are subject to strong phase mixing, which leads to the
18 development of thermal pressure anisotropy. This anisotropy triggers the Weibel instability, which
19 produces filamentary “seed” magnetic fields on plasma-kinetic scales. The plasma is thereby magne-
20 tized, enabling efficient stretching and folding of the fields by the plasma motions and the development
21 of Larmor-scale kinetic instabilities such as the firehose and mirror. The scattering of particles off the
22 associated microscale magnetic fluctuations provides an effective viscosity, regulating the field morphol-
23 ogy and turbulence. During this process, the seed field is further amplified by the fluctuation dynamo
24 until they reach energy equipartition with the turbulent flow. By demonstrating that equipartition
25 magnetic fields can be generated from an initially unmagnetized plasma through large-scale turbulent
26 flows, this work has important implications for the origin and amplification of magnetic fields in the
27 intracluster and intergalactic mediums.

28 *Keywords:* Magnetogenesis – turbulence – dynamo – intracluster medium

29 1. INTRODUCTION

30 The origin and evolution of cosmic magnetic fields is
31 one of the most important long-standing problems in
32 astrophysics and cosmology (Kulsrud & Zweibel 2008;
33 Brandenburg & Ntormousi 2023). In galaxies and clus-
34 ters of galaxies, large-scale magnetic fields with up
35 to micro-Gauss strengths are found to be ubiquitous
36 through observations of Faraday rotation, synchrotron
37 emission, and Zeeman splitting (e.g., Beck et al. 1996;
38 Carilli & Taylor 2002; Bonafede et al. 2010). The
39 amplification of pre-existing “seed” magnetic fields—
40 **they cosmological, proto-galactic, and/or plasma-kinetic**
41 **in origin**—by dynamo action is believed to be essen-
42 tial in producing such dynamically important magnetic
43 fields. In contexts such as the intracluster medium

44 (ICM) of galaxy clusters, the dynamo is thought to pro-
45 ceed through successive stretching of magnetic fields by
46 (gravitationally driven) chaotic flows, resulting on the
47 average in amplification of the magnetic energy **via mag-**
48 **netic induction to levels comparable to the kinetic en-**
49 **ergy of the flows.**

50 Plasma dynamos have been studied extensively within
51 a magnetohydrodynamic (MHD) framework (Subrama-
52 nian et al. 1994; Brandenburg & Subramanian 2005;
53 Rincon 2019), but only recently using a kinetic frame-
54 work (Rincon et al. 2016; St-Onge & Kunz 2018; Pusztai
55 et al. 2020), even though a kinetic treatment of the dy-
56 namo is important because cosmic plasmas are typically
57 weakly collisional, i.e., the particles’ Coulomb mean free
58 paths are comparable to or even exceed the characteris-
59 tic macroscopic length scale of an astrophysical system.
60 Under such conditions, the influence of micro-physical
61 plasma processes on the dynamo is potentially signif-
62 icant. For example, hybrid-kinetic (kinetic ions, fluid

electrons) studies of the dynamo (Rincon et al. 2016; St-Onge & Kunz 2018) have shown that micro-scale kinetic instabilities determine the effective viscosity of the turbulent plasma and, in so doing, control the amplification rate of any seed magnetic field. Going further—namely, realizing a self-consistently generated seed field and capturing the influence of collisionless electrons—requires a fully kinetic treatment of the dynamo process. This is the purpose of this paper.

In a weakly collisional plasma, anisotropy in the thermal motions of the particles provides free energy to create magnetic fields from an initially unmagnetized state through the Weibel instability (e.g., Weibel 1959; Pucci et al. 2021; Zhou et al. 2022). As the Weibel fields grow to deplete this thermal free energy, the plasma ultimately becomes magnetized, and the bulk flow is then able to stretch and fold the magnetic field to increase its overall strength. The approximate conservation of the adiabatic invariant of the magnetic moments μ by the magnetized particles implies that the growth of the magnetic field will again bias the thermal motion of the plasmas, but now with respect to the magnetic-field direction. This field-biased pressure anisotropy serves as a source of free energy for the mirror and firehose plasma instabilities. The scattering of particles off the Larmor-scale fluctuations driven by these two instabilities plays an important role for the plasma dynamo by controlling the plasma viscosity (and possibly resistivity as well) (Kunz et al. 2014; St-Onge & Kunz 2018), and by breaking the adiabatic invariance of μ , the conservation of which in the absence of pitch-angle scattering would place a prohibitive constraint on the energy budget for the growth of magnetic fields (Helander et al. 2016).

In this work, we develop a fully kinetic, self-consistent description of the generation and amplification of magnetic fields in an initially unmagnetized plasma under large-scale chaotic motions. In Section 2, we discuss our theoretical expectations for four distinguishable phases of the *ab-initio* plasma dynamo, as well as the scale separation required between the macroscopic flows and the electron plasma skin depth to capture these phases in a numerical simulation. We then present results from particle-in-cell (PIC) simulations of the plasma dynamo in Section 3, which we find to be qualitatively consistent with the theoretical expectations. We conclude in Section 4 with a brief discussion on the properties of a fully kinetic dynamo and how our results might fit into the broader narrative of cosmic magnetogenesis.

In a collisionless plasma, kinetic instabilities often play an essential role in generating seed magnetic fields and regulating the material properties of the plasma, e.g., its effective dynamical viscosity, thermal conductivity, and electrical resistivity (Kunz et al. 2019). The interplay between this microscale physics, and its macroscale consequences for the establishment of turbulent flows and the amplification and sustenance of cosmic magnetic fields, are central ingredients in any predictive theory for the plasma dynamo. In this section, we review some of this physics, taking care to distinguish between what has been rigorously established and what is more speculative.

We first define three dimensionless quantities to describe the energetics of the system. The first, which quantifies the average magnetic energy density in the plasma, is the (inverse) plasma beta parameter, $\beta^{-1} \equiv \langle B^2/8\pi \rangle / \langle P \rangle$, where P is the plasma pressure and $\langle \cdot \rangle$ denotes the domain average. The bulk flow energy is quantified using the square of the Mach number, $M^2 \equiv (U_{\text{rms}}/v_{\text{th}})^2$, with U_{rms} being the root-mean-square bulk flow speed and $v_{\text{th}} \equiv \sqrt{\langle P/\rho \rangle}$ being the thermal speed, with ρ the total mass density. The free thermal energy of the plasma is represented by the pressure anisotropy, $\Delta \equiv \langle P_{\perp}/P_{\parallel} - 1 \rangle$, where P_{\perp} (P_{\parallel}) is the thermal pressure perpendicular (parallel) to the local magnetic field. This definition presumes a magnetized plasma; when the plasma is unmagnetized, the relevant pressure anisotropy is that measured with respect to the axis along which the pressure tensor has its maximum eigenvalue (see Zhou et al. (2022) for details). In the Weibel-seeded plasma dynamo, there are two ways in which pressure anisotropy is produced. The first, most relevant to the early unmagnetized stage, issues from the collisionless phase mixing of the driven shear flows (Zhou et al. 2022). Unmagnetized particles carrying the momentum of the local bulk flows have random thermal motions. The free streaming of these particles smooths out the spatial variation of the bulk flows and leads to the development of velocity-space anisotropy in particle distributions and thus pressure anisotropy. The second means of producing pressure anisotropy requires the plasma to be magnetized, as it relies on the adiabatic invariance of the particles' magnetic moments $\mu \equiv mv_{\perp}^2/2B$, where m and v_{\perp} are the mass and perpendicular velocity of each particle, to couple their perpendicular thermal energy to the magnetic-field strength. Consequently, as the bulk flows stretch and amplify the magnetic field, P_{\perp} increases relative to P_{\parallel} . Once produced, Δ provides a free-energy source for driving rapidly growing kinetic instabilities, predominantly in the form of skin-depth- or Larmor-scale magnetic fluc-

2. THEORETICAL EXPECTATIONS

tuations. The scattering or trapping of particles as they interact with these fluctuations leads to an effective dynamical viscosity (in addition to that caused by phase mixing and particle collisions), which in turn constrains the large-scale flows.

In what follows, we provide estimates for the evolution of β^{-1} given driven turbulence characterized by Mach number M and characteristic scale L . With asymptotically large scale separation between the macroscopic astrophysical flows and the microscopic plasma kinetic scales, we anticipate four main phases of magnetic-field amplification, as illustrated schematically in Figure 1 and detailed in the following subsections.

Figure 1: A qualitative illustration of the predicted time evolution of β^{-1} (or magnetic energy) in the Weibel-seeded, turbulent plasma dynamo, divided into four main phases. Reference values of the predicted magnetic-field strength given ICM conditions are given on the ordinate.

2.1. Seeding of magnetic fields by Weibel instability

The Weibel instability has been recognized and widely studied as a mechanism to generate magnetic fields. It is particularly versatile, as its only requirement is pressure anisotropy in an unmagnetized plasma. Despite this versatility, the Weibel instability has been studied mainly in the context of local counter-streaming configurations such as collisionless shocks (e.g., Medvedev & Loeb 1999; Spitkovsky 2008; Kato & Takabe 2008; Medvedev et al. 2006) and laser-plasma interactions (e.g., Schoeffler et al. 2014; Huntington et al. 2015), and has only recently been considered in the more global context of low-Mach-number turbulence, e.g., in galaxy clusters and the intergalactic medium (Zhou et al. 2022). In this paper, we are concerned with the latter case.

Zhou et al. (2022) presented an analytical and numerical investigation of the development and saturation of the Weibel instability in an electron-positron plasma

under the action of a large-scale shear flow (as a local approximation of a turbulent system). In an initially unmagnetized plasma, any inhomogeneous flow is subject to efficient phase mixing via the thermal motions of the particles. This phase mixing leads to the development of free energy in the plasma in the form of a pressure anisotropy that increases on a hybrid thermal-dynamic time scale, $\Delta \simeq M(tv_{\text{th}}/L)^2$. In response to this slowly evolving background, the fast, kinetic-scale electron Weibel instability is triggered, with an instantaneous linear growth rate $\gamma_w \simeq \Delta^{3/2}\omega_{\text{pe}}v_{\text{th}}/c$ for the most unstable linear mode $k_w \simeq \Delta^{1/2}/d_e$, where $\omega_{\text{pe}} \equiv \sqrt{4\pi ne^2/m_e}$ is the plasma frequency and $d_e \equiv c/\omega_{\text{pe}}$ is the electron skin depth. In consideration of this electron-only (or electron-positron) Weibel instability, Δ and M in these expressions are defined using the electron thermal speed. As Δ increases slowly, the linear growth rate of the Weibel instability also increases, and the magnetic perturbations grow super-exponentially (Zhou et al. 2022). This rapid growth proceeds until the instability enters a nonlinear regime in which the depletion of the free energy (quantified by Δ) by the instability balances its replenishment by the persistent phase mixing of the bulk momentum. In this nonlinear regime, the spontaneously produced magnetic field continues its growth, but with a decreased growth rate. At some point this field begins to affect the trajectories of the particles and eventually magnetize the plasma. The instability then reaches saturation when the electron Larmor radius $\rho_e \equiv m_e v_{\text{th}} c / eB$ decreases to become comparable to the coherence scale of the Weibel seed field, $\rho_e k_w \sim 1$; this is known as the trapping condition (Davidson et al. 1972; Kato 2005).

The dependence of the saturated magnetic energy ($\propto \beta^{-1}$) and coherence scale ($\propto k_w^{-1}$) of the Weibel seed field on the scale separation L/d_e and the Mach number were found to be given by (Zhou et al. 2022)

$$\beta_w^{-1} \sim (L/d_e)^{-1/2} M^{1/4}, \quad (1)$$

$$k_w d_e \sim (L/d_e)^{-1/4} M^{1/8}. \quad (2)$$

These results set the expectation that, under the generic motions of astrophysical turbulence, seed magnetic fields are automatically generated through the Weibel instability and plasmas are spontaneously magnetized. Without making additional assumptions on the origins of seed fields, the β_w^{-1} given by Eq. (1) provides a lower bound on the seed magnetic energy for any turbulent dynamo.

The above discussion only considered the electron Weibel instability. In reality, as the ions develop a pressure anisotropy of their own, they should also become unstable to a Weibel instability, which would produce magnetic fields on the ion-kinetic scales. Because the

246 detailed effects of the magnetized electrons on this ion
 247 Weibel instability are still unclear at this time, we sim-
 248 ply assume that the magnetic energy and wavenumber
 249 of the ion Weibel fields should obey the same scaling
 250 as Eqs. (1)–(2), with d_e replaced by the ion skin depth
 251 d_i and M defined using the ion thermal speed. Adopt-
 252 ing these replacements would boost the value of β_w^{-1} at
 253 the end of the ion-Weibel stage by a relatively modest
 254 factor of $(m_i/m_e)^{3/8} \approx 17$, and the value of k_w given
 255 by the ion Weibel field would decrease by a factor of
 256 $(m_i/m_e)^{5/16} \approx 10$. For the remainder of this section,
 257 we assume that there is a phase of ion-Weibel growth
 258 of the magnetic field; the numerical experiments pre-
 259 sented in Section 3 adopt an electron-positron plasma,
 260 for which no such phase exists.

261 2.2. Inverse cascade of the Weibel seed field

262 Because the Weibel field is produced on a time scale
 263 much shorter than the flow-crossing time scale $\sim L/U_{\text{rms}}$,
 264 the impact of the large-scale shear flow on its initial
 265 evolution is only minimal. The Weibel field is thus ex-
 266 pected to evolve without directly interacting with the
 267 background flow for $t \lesssim L/U_{\text{rms}}$. It has been repeat-
 268 edly found that these Weibel fields, after their formation
 269 and saturation, will coalesce and increase their coher-
 270 ence length (e.g., Gruzinov 2001; Medvedev et al. 2005;
 271 Kato & Takabe 2008; Zhou et al. 2022), that is, inverse-
 272 cascade to larger scales. In order to predict the proper-
 273 ties of these fields at the moment they become seeds for
 274 a fluctuation dynamo (i.e., at $t \sim L/U_{\text{rms}}$), it is essential
 275 to know what scale the Weibel fields can reach through
 276 coalescence within one flow-crossing time, and how their
 277 magnetic energy evolves during this inverse cascade.
 278 Zhou et al. (2019, 2020, 2021) derived a simplified an-
 279 alytical model based on fundamental conservation laws
 280 to describe the evolution of initially small-scale magnetic
 281 fields during their successive coalescence¹. Those au-
 282 thors identified magnetic reconnection as the key mech-
 283 anism enabling the growth of magnetic fields' character-
 284 istic length scale and setting the associated time scale.
 285 They found that the decay of magnetic energy and the
 286 growth of the coherence length of the magnetic fields (or,
 287 equivalently, the decrease of its corresponding wavenum-
 288 ber k) are described by scalings

$$\beta^{-1} \sim \beta_w^{-1} (t/\tau_{\text{rec}})^{-1}, \text{ and } k \sim k_w (t/\tau_{\text{rec}})^{-1/2}, \quad (3)$$

¹ Their study was conducted using the resistive-MHD equations,
 but the conservation laws they used to derive the scalings for
 the evolution of the system are expected to hold more generally
 (beyond a fluid description)

289 respectively. Here $\tau_{\text{rec}} \equiv \epsilon_{\text{rec}}^{-1} \sqrt{\beta_w} / (k_w v_{\text{th}})$ is the recon-
 290 nection time scale for the initial fields (i.e., the satu-
 291 rated Weibel fields with energy β_w^{-1} and wavenumber
 292 k_w) and ϵ_{rec} is the dimensionless reconnection rate; val-
 293 ues of $\epsilon_{\text{rec}} \sim 0.1$ are usually found in numerical stud-
 294 ies of reconnection in a collisionless, well-magnetized
 295 plasma (e.g., Daughton & Karimabadi 2007; Daughton
 296 et al. 2011) (although the detailed physics of magnetic
 297 reconnection in the high- β regime is still unclear).

298 Combining Eqs. (1)–(3), we obtain the energy and in-
 299 verse length scale of the coalescing Weibel filaments at
 300 $t \sim L/U_{\text{rms}}$:

$$\beta_{\text{seed}}^{-1} \sim (L/d_i)^{-1} M \epsilon_{\text{rec}}^{-1}, \quad (4)$$

$$k_{\text{seed}} d_i \sim (L/d_i)^{-1/2} M^{1/2} \epsilon_{\text{rec}}^{-1/2}. \quad (5)$$

302 In a typical ICM, $M \sim 0.1$ (and so $M \epsilon_{\text{rec}}^{-1} \sim 1$) and
 303 $L/d_i \sim 10^{14}$. If the above scalings are correct, the rem-
 304 nant Weibel seed fields at the end of the inverse cascade
 305 process would have an energy of only $\beta_{\text{seed}}^{-1} \sim 10^{-14}$
 306 and reside on length scales much larger than the kinetic
 307 scales, $k_{\text{seed}} d_i \sim 10^{-7}$. Note that, during this process,
 308 the ratio of the particles' Larmor radii ($\rho_i \propto \beta^{1/2}$) and
 309 the coherence scale of the magnetic field, viz., $\rho_i k \sim$
 310 $\beta_w^{1/2} k_w$, remains a constant. That is, after the particles
 311 become magnetized at the saturation of Weibel fields,
 312 they remain magnetized during the inverse cascade of
 313 these fields.

314 2.3. Accelerating dynamo

315 At $t \sim L/U_{\text{rms}}$, the large-scale plasma flow is estab-
 316 lished and the coalescence of the Weibel fields is re-
 317 placed by the stretching and folding of the field lines
 318 by the flow. The adiabatic conservation of the mag-
 319 netic moment μ during this stretching implies the gener-
 320 ation of pressure anisotropy. As the pressure anisotropy
 321 grows, the magnetized plasma becomes unstable to ki-
 322 netic plasma instabilities, namely the mirror (Shapiro
 323 & Shevchenko 1964; Barnes 1966; Southwood & Kivel-
 324 son 1993; Hellinger 2007) and the firehose (Rosenbluth
 325 1956; Chandrasekhar et al. 1958; Parker 1958; Vedenov
 326 & Sagdeev 1958; Yoon et al. 1993; Hellinger & Mat-
 327 sumoto 2000) (the ion cyclotron instability may also
 328 play a role when $\Delta > 0$ (Riquelme et al. 2015)). The
 329 mirror instability, with the threshold $\Delta \gtrsim 1/\beta$, should
 330 occur in regions where the field lines are stretched and
 331 the field strength increases; the firehose instability, with
 332 the threshold $\Delta \lesssim -2/\beta$, should occur in regions where
 333 the field lines are bent (which, in the fluctuation dy-
 334 namo, are statistically also where the field strength has
 335 decreased (Schekochihin et al. 2004)).

336 After these instabilities grow and saturate, particles

scatter off of the associated Larmor-scale distortions in the magnetic field and isotropize the velocity distribution. This scattering can be interpreted as an effective collisionality (Kunz et al. 2014; Riquelme et al. 2015), which we denote as ν_{eff} , and which supplants the (typically slower) Coulomb collisionality ν_c . Following the Chew–Goldberger–Low equations (Chew et al. 1956), assuming incompressibility, and taking into account the isotropizing effect of the effective collisions (Schekochihin & Cowley 2006; Rosin et al. 2011), the evolution of Δ with $|\Delta| \lesssim 1/\beta \ll 1$ can be written heuristically as

$$\frac{d\Delta}{dt} \approx 3 \frac{d \ln B}{dt} - \nu_{\text{eff}} \Delta. \quad (6)$$

This equation states that pressure anisotropy is produced through adiabatic invariance and relaxed by an effective collisionality.

In a turbulent environment, the spatio-temporal inhomogeneity of the fluctuations, the pressure anisotropy, and thus the effective collisionality complicate a detailed description of the plasma dynamo. What follows in the remainder of this subsection and the next one (Section 2.4) is a scenario for the inductive phase of the plasma dynamo, one that is based on a combination of theoretical arguments and results from existing hybrid-kinetic simulations of this phase.

We begin by associating an effective parallel Reynolds number $\text{Re}_{\parallel} \equiv U_{\text{rms}} L / (v_{\text{th}}^2 / \nu_{\text{eff}})$ with the effective collisionality, which for $\nu_{\text{eff}} > \nu_c$ is larger than the Reynolds number associated with Coulomb collisions. Because Re_{\parallel} determines the maximum value of the field-parallel rate of strain of the flow, $\mathbf{bb} : \nabla \mathbf{u}$, it also controls the amplification rate of the magnetic field. Assuming the Kolmogorov scaling (Kolmogorov 1941) for the turbulent flow (which is not *a priori* guaranteed but finds support in existing hybrid-kinetic simulations (St-Onge & Kunz 2018)), the parallel rate of strain is largest at the parallel viscous scale $\ell_{\nu\parallel} \sim L \text{Re}_{\parallel}^{-3/4}$. The parallel rate of strain, and thus the growth rate of magnetic fields, can then be expressed as

$$\gamma \equiv \frac{d \ln B}{dt} \simeq \mathbf{bb} : \nabla \mathbf{u} \sim \frac{U_{\text{rms}}}{L} \text{Re}_{\parallel}^{1/2}. \quad (7)$$

In what follows, we adopt (and adapt) arguments made by Schekochihin & Cowley (2006) for how the dependence of Re_{\parallel} on the magnetic-field strength through the action of these kinetic instabilities might lead to an accelerating dynamo and explosive growth of magnetic fields (phase III).

As the flows stretch and amplify the magnetic fields, the mirror and firehose instabilities are triggered and their associated fluctuations grow. In the early phase of

the dynamo, when magnetic fields are sufficiently weak, the scattering rate needed to regulate Δ to within the firehose and mirror thresholds is larger than the ion Larmor frequency, that is, $|\mathbf{bb} : \nabla \mathbf{u}| / \Delta \gg \Omega_i$. Such a collisionality cannot be realized, i.e., the kinetic instabilities cannot scatter particles so fast that the plasma de-magnetizes. In this regime, it is reasonable to believe that the particle scattering rate is controlled by the growth rate of the mirror and firehose instabilities, both of which are proportional to the Larmor frequency times some power of the pressure anisotropy. We therefore write $\nu_{\text{eff}} \propto B^\alpha$ with α being positive (Schekochihin & Cowley 2006; Melville et al. 2016). Then, the dynamo growth rate $d \ln B / dt \propto \text{Re}_{\parallel}^{1/2} \propto \nu_{\text{eff}}^{1/2} \propto B^{\alpha/2}$ increases with increasing field strength, resulting in an explosive growth of magnetic energy (characterized by a finite-time-singularity):

$$\beta^{-1} = \beta_{\text{seed}}^{-1} \left[1 - \frac{\alpha U_{\text{rms}}}{2 L} \text{Re}_{\parallel 0}^{1/2} (t - t_{\text{seed}}) \right]^{-2/\alpha}, \quad (8)$$

where $t_{\text{seed}} \sim L / U_{\text{rms}}$ indicates the moment of time at the beginning of this explosive phase. Here $\text{Re}_{\parallel 0}$ is the parallel Reynolds number at this time, which is expected to be provided by phase mixing, collisions between particles, and/or the weak scattering off Weibel fluctuations, with an estimated value of $\text{Re}_{\parallel 0} \sim \mathcal{O}(1)$. Given the form of Eq. (8), the actual value of α does not affect the main feature of this phase. At the early time of this stage ($t - t_{\text{seed}} \ll L / U_{\text{rms}}$), the magnetic energy grows linearly $\beta^{-1} = \beta_{\text{seed}}^{-1} [1 + (U_{\text{rms}} / L) \text{Re}_{\parallel 0}^{1/2} (t - t_{\text{seed}})]$. The dynamo amplification starts to accelerate as it evolves with time and the explosive phase ends at around $(\alpha/2)(U_{\text{rms}} / L) \text{Re}_{\parallel 0}^{1/2} (t - t_{\text{seed}}) \sim 1$. Because both α and $\text{Re}_{\parallel 0}$ are order-unity numbers, this phase III is expected to last for $(t - t_{\text{seed}}) \sim L / U_{\text{rms}}$, roughly one more flow-crossing time. This phase of accelerating dynamo growth, although being short, is critical to the overall amplification of magnetic fields because it allows the Re_{\parallel} , and thus the dynamo growth rate, to increase to a comparatively large value. Note that this phase has not yet been clearly realized in kinetic simulations, though finds some support in dedicated studies of the firehose and mirror (Melville et al. 2016).

2.4. Pressure-anisotropy-instability regulated dynamo.

As the nonlinear mirror and firehose fluctuations continue to grow alongside the dynamo field, the scattering of particles eventually becomes efficient enough to regulate the plasma anisotropy to values comparable to the instabilities' thresholds, *viz.* $|\Delta| \sim 1/\beta$. We may then use Eq. (6) to estimate the value of ν_{eff} required for this to occur, namely, $\nu_{\text{eff}} \approx |\mathbf{bb} : \nabla \mathbf{u}| \beta$. (Such a collision-

ality has been measured directly in the later stages of the plasma dynamo using hybrid-kinetic simulations; (St-Onge & Kunz 2018.) The transition to this phase occurs when the increasing Larmor frequency (as the magnetic field grows) becomes comparable to this required collisionality, *viz.* $\Omega_i \sim |\mathbf{bb} : \nabla \mathbf{u}| \beta$, which is equivalent to the requirement that (St-Onge et al. 2020)

$$\beta_{\text{ani}}^{-1} \sim (L/d_i)^{-2/5} M^{6/5}. \quad (9)$$

Once this level of magnetic energy is reached, the hypothesized phase of explosive growth should end and the dynamo will start to be regulated by the pressure-anisotropy-instability (phase IV). Under typical ICM conditions, this value of β_{ani}^{-1} corresponds to $\sim \text{nG}$ fields. That is, the magnetic fields are expected to be amplified to have a similar amount of energy as the Weibel fields before they coalesced and decayed, but presumably with a much larger coherence scale than the Weibel fields. This phase of dynamo starts with a large effective Re_{\parallel} and thus the strength of the magnetic fields increases significantly. As derived and numerically confirmed in Melville et al. (2016); St-Onge & Kunz (2018), the expression for the collisionality $\nu_{\text{eff}} \approx 3|\mathbf{bb} : \nabla \mathbf{u}| \beta$ when the anisotropy is regulated suggests that

$$\text{Re}_{\parallel} \sim \nu_{\text{eff}} U_{\text{rms}} L / v_{\text{th}}^2 \sim M^4 \beta^2. \quad (10)$$

That is, as magnetic fields are amplified by this pressure-anisotropy-instability-regulated dynamo, the parallel Reynolds number, and thus the parallel rate of strain, keeps decreasing. [Note that Eq. (10) implies a parallel viscous scale that is commensurate with the scale on which the flow is Alfvénic, and so the dynamo is intrinsically nonlinear during this phase.] The amplification of the magnetic field thus gradually slows down. This phase eventually ends either when the dynamo saturates with approximate equipartition between the mean kinetic and magnetic energies, *viz.* $\beta_{\text{sat}}^{-1} \sim M^2$ and $\text{Re}_{\parallel} \sim 1$, or when the effective collisionality drops below the background Coulomb collisionality and the plasma is no longer kinetically unstable, *viz.* $\beta_{\text{sat}}^{-1} \lesssim M^{3/2} (\lambda_{\text{mfp},c}/L)^{1/2}$. In the latter case, the magnetic fields would continue to be amplified to equipartition. Coincidentally or not, the ICM seems to reside near the boundary between these two cases, with $\beta^{-1} \sim 10^{-3}$ – 10^{-2} , $M \sim 0.1$, and $\lambda_{\text{mfp},c}/L \sim 10^{-2}$ – 10^{-1} , and thus the anomalous scattering from the putative firehose/mirror instabilities is comparable to Coulomb scattering.

Though the aforementioned processes (except for the explosive phase) have been investigated independently with specific set-ups, how they transition from one to the other and how they collectively shape the collisionless turbulent dynamo is still unclear. In Sec-

tion 3, we present a numerical study that aims to include self-consistently all the relevant physical processes (for the case of a pair plasma). Unfortunately, quite a large scale separation L/d_i is required to satisfy both $\beta_{\text{seed}}^{-1} \ll \beta_{\text{ani}}^{-1} \ll \beta_{\text{sat}}^{-1}$ and $\beta_{\text{seed}}^{-1} \ll \beta_w^{-1}$, and distinguish between all of the hypothesized four phases of evolution. Using $M \sim 0.1$ and assuming these critical values of β^{-1} are separated by at least a factor of 10, we require that $L/d_i \gtrsim 10^5$. This requirement vastly exceeds that which can be achieved with today’s computational resources [the cost of a simulation scales as $(L/d_i)^4$], and the simulation discussed in the next section is only able to provide qualitative evidence for many of these theoretical predictions. In particular, phase II and III are barely captured in the simulation and the numerical evidence can only serve as a test of consistency with the above theoretical expectations.

3. NUMERICAL EXPERIMENTS

3.1. Numerical methods

We perform fully kinetic, particle-in-cell (PIC) simulations to study the plasma dynamo with the code *Zeltron* (Cerutti et al. 2013). Because of the high computational cost inherent to this problem, our simulations are performed with an electron-positron plasma, in which the skin depths of both species are identical, as are their Larmor-radius scales. The system is initialized with a spatially uniform, isotropic, unmagnetized, Maxwell–Jüttner plasma of sub-relativistic temperature $T_{e0} \equiv \theta_e mc^2 = 1/16$. It is continuously subjected to a random, time-correlated external volumetric mechanical force, \mathbf{F}_{ext} , applied at the largest scales of the domain (Zhdankin 2021) (details in Appendix A.1). The force \mathbf{F}_{ext} contains six solenoidal modes with time-dependent random phases and is designed to drive incompressible flows. Optically thin external inverse Compton (IC) radiative cooling (parameters described in Appendix A.2) is included to achieve a steady temperature close to T_{e0} and to suppress non-thermal particle acceleration by cooling mainly at the high-energy tails of the plasma distributions. The IC radiation is isotropic and thus is not expected to affect the properties of the plasma dynamo. The simulation is performed in a 3D periodic cubic box and the separation between the domain scale (L) and the plasma skin depth (d_e) is $L/d_e = 378$, so that the total number of cells is 1512^3 . We use 32 particles per cell (PPC) (16 per species) for the simulation and so around 100 billion particles in total. Simulations with PPC ranging from 32 to 128 show the same results. The grid spacing is uniform with $dx (= dy = dz) = \lambda_{\text{De}} = d_e/4$, where λ_{De} is the (initial) Debye length and $d_e/\lambda_{\text{De}} = \sqrt{1/\theta_e} = 4$.

3.2. Numerical results

The overall evolution of the system in our simulation can be divided into four qualitatively different stages: the linear Weibel stage ($tU_{\text{rms}}/L \lesssim \tau_w$), the Weibel-filament coalescing stage ($\tau_w < tU_{\text{rms}}/L \lesssim 1$), the exponential dynamo stage ($1 < tU_{\text{rms}}/L \lesssim 3$), and then slow amplification until saturation ($3 \lesssim tU_{\text{rms}}/L \lesssim 7$). The first and second of these stages correspond to Phase I (Sec. 2.1) and Phase II (Sec. 2.2), respectively, of our theoretical expectations. The third and fourth of these stages correspond to Phase IV (Sec. 2.4) of our theoretical expectations. Note that Phase III (Sec. 2.3) of our theoretical expectations is not clearly realized in the PIC simulations due to limited scale separation, as discussed below.

3.2.1. Generation and evolution of seed magnetic fields

The energetics of the system are described by the time evolution of β^{-1} , M^2 , and Δ (defined as described in Section 2 but instead using the electron mass and electron thermal speed), shown in the top panel of Figure 2. As the plasma is stirred by the applied force, bulk motions are established and M^2 increases. The phase mixing of the inhomogeneous flows by the thermal motion of the particles leads to the development of pressure anisotropy Δ . In an unmagnetized plasma, this anisotropy triggers the Weibel instability (Weibel 1959; Fried 1959) and generates the seed magnetic fields (Phase I of Sec. 2.1), as indicated by the rapid increase of β^{-1} . The Weibel instability reaches its nonlinear phase and the Weibel filaments become prominent at a time that we denote as τ_w ($\approx 0.16L/U_{\text{rms}}$; vertical dotted line), at which point the morphology of the magnetic field is shown in the left panel of Figure 3. Clear filamentary structures of the Weibel fields on $\sim d_e$ scales emerge from the initial random noise and occupy an appreciable fraction of the volume of the domain. We refer readers interested in the finer details of Weibel growth and saturation to Zhou et al. (2022), where these phases are studied using the simplified setup of a large-scale shear flow; our present simulation and those in Zhou et al. (2022) exhibit very similar evolution during these two phases despite differences in driving parameters.

The time evolution (over the whole simulation) of magnetic and bulk kinetic energy spectra [integrated on spherical shells in wavenumber (\mathbf{k}) space], $\mathcal{M}(k) \equiv (1/4\pi) \int d\Omega_k k^2 |\mathbf{B}(\mathbf{k})|^2 / 8\pi$ (blue lines) and $\mathcal{K}(k) \equiv (1/4\pi) \int d\Omega_k k^2 |\mathbf{u}(\mathbf{k})|^2 / \rho / 2$ (orange lines), is shown in Figure 4, with earlier times corresponding to curves with greater transparency. The magnetic (kinetic) spectra with blue (orange) curves are highlighted in the top (bottom) panel, with the other one shown in the back-

Figure 2: Top: time evolution of M^2 , Δ , and β^{-1} . Bottom: time evolution of magnetic energy density at various wavenumbers. The vertical dotted line indicates the time τ_w when the Weibel instability reaches its largest growth rate.

ground for reference.² At early times (around τ_w), the bulk kinetic energy concentrates at the system scale, with little energy cascading to the smaller scales. This is consistent with the expectation that a collisionless, unmagnetized plasma is very viscous with the effective $\text{Re}_{\parallel} \sim 1$ due to unimpeded phase mixing. The magnetic energy spectrum at τ_w (highlighted with the magenta curve) peaks at $k_w L/2\pi \approx 20$, i.e., a wavenumber $k_w \approx 0.3/d_e$.

The scaling dependence of the saturated amplitude and length scale of the Weibel seed fields on the rate of strain of the flow (U_{rms}/L) and the scale separation (L/d_e), as determined by Zhou et al. (2022), is given by Eq. (1). With the limited scale separation in our simulation, we expect the Weibel instability to produce seed fields with energy $\beta_w^{-1} \simeq 10^{-2}$ and wavenumber $k_w d_e \simeq 0.2$. This is roughly consistent with our

² The spectral bumps at large $kL/2\pi$ (corresponding to length scales comparable to λ_{De}) are caused by numerical noise. They do not affect the simulation given their low amplitudes and concentration at high k .

Figure 3: Visualization of (normalized) magnetic field magnitude at peak Weibel growth ($tU_{\text{rms}}/L = \tau_w$; left), after one large-scale turnover time ($t = L/U_{\text{rms}}$; middle), and in the saturated state of the dynamo (right).

598 measured $\beta^{-1} \approx 3 \times 10^{-3}$ (Figure 2) and $k_w d_e \approx 0.3$ 634
 599 (Figure 4) at τ_w . For comparison, using a value of 635
 600 $L/d_e \sim 10^{16}$ characteristic of the bulk ICM in Eq. (1) 636
 601 predicts $\beta_w^{-1} \sim 10^{-8}$. 637

602 After τ_w , the system enters the second stage in which 638
 603 the nonlinear effects of the Weibel instability become 639
 604 important (Phase II of Sec. 2.2). The peak of the mag- 640
 605 netic spectrum shifts to lower k while continuing to grow 641
 606 in amplitude. Two effects are responsible for this shift. 642
 607 The first is due to the low- k Weibel modes. While the 643
 608 high- k , fastest-growing Weibel modes become nonlinear 644
 609 and stop growing exponentially, the initially subdomi- 645
 610 nant longer-wavelength Weibel modes are still in the 646
 611 linear stage and continue to grow exponentially, albeit 647
 612 with a lower linear growth rates, and thus start to over- 648
 613 take the high- k modes. The second, as described in Sec- 649
 614 tion 2.2, the Weibel filaments, after they saturate, are 650
 615 expected to start to coalesce with one another via recon- 651
 616 nection (Zhou et al. 2020, 2022) before being affected by 652
 617 the flow shear on the time scale $\sim L/U_{\text{rms}}$. As we men- 653
 618 tion at the end of Section 2, the coalescence phase is 654
 619 difficult to identify unambiguously in the simulation be- 655
 620 cause of the limited scale separation. Some coalescence 656
 621 events can be seen in the middle panel of Figure 5, which 657
 622 plots representative field lines chosen from regions with 658
 623 strong magnetic fields at $t = 0.3L/U_{\text{rms}}$. At multiple lo- 659
 624 cations, distinct filaments are nested within shared field 660
 625 lines, suggesting an ongoing coalescence. Through this 661
 626 process, the coherence length scale of the magnetic fields 662
 627 grows and the magnetic energy dissipates rapidly. This 663
 628 can also be seen in the time evolution of magnetic en- 664
 629 ergy densities at different k , shown in the bottom panel 665
 630 of Figure 2. Initially, the fastest growing modes occur 666
 631 at around $kL/2\pi \approx 20$ (i.e., at wavenumber k_w). These 667
 632 modes saturate quickly (at around τ_w), and are immedi- 668
 633 ately followed by a sudden drop of their energy densities

634 due to filament coalescence, coinciding with a jump in 635
 636 energy density at smaller wavenumbers by a factor of $\sqrt{2}$ 637
 638 (consistent with flux conservation; e.g., Gruzinov 2001; 639
 640 Zhou et al. 2020). 641

642 With sufficient length scale separation L/d_e (and 643
 644 hence $k_w L$) and time scale separation between τ_w 645
 646 and L/U_{rms} , we anticipate a prolonged phase of succes- 647
 648 sive coalescence of Weibel filaments. The decay of mag- 649
 650 netic energy and the growth of coherence length scale 651
 652 during such a phase is expected to follow the scaling 653
 654 laws given by Eq. (3). In our simulation, only a couple 655
 656 of generations of coalescence are allowed before being 657
 658 interrupted by the flow shear and this predicted phase 659
 660 in which β^{-1} decreases is not well captured. 661

3.2.2. Establishment of plasma dynamo

649 After the phase of Weibel growth and magnetization 650
 651 of the plasma, the system is continuously driven by 652
 653 the external force towards reaching a statistical steady 654
 655 state. As shown in the top panel of Figure 2, both 656
 657 M^2 and Δ continue to increase and attain steady val- 658
 659 ues by $t \approx L/U_{\text{rms}}$. On this flow-crossing time scale, 660
 661 the large-scale flows are fully developed and start to 662
 663 stretch and deform the seed fields. The (coalesced) 664
 665 Weibel seed fields reorganize, aligning with the large- 666
 667 scale flows, as shown in the middle panel of Figure 3. 668
 669 The magnetic and kinetic energy spectra at $t = L/U_{\text{rms}}$ 669
 670 are highlighted in Figure 4 with green curves. The ki- 670
 671 netic spectrum rapidly extends towards smaller scales, 671
 672 with a knee forming at $kL/2\pi \approx 5$, where the kinetic 672
 673 and magnetic energy are comparable. Below the knee, a 673
 674 shallower kinetic spectrum is formed, where a $k^{-5/3}$ line 674
 675 is included as a visual reference. The broadening of the 675
 676 kinetic spectrum indicates that some energy is cascading 676
 677 to smaller scales and suggests the formation of a viscous 677
 678 scale slightly smaller than the outer scale. The magnetic 678
 679 spectrum is also broadened due to the combined effect of 679

Figure 4: Magnetic (blue) and bulk kinetic (orange) energy spectra at various times, with earlier times corresponding to lines with greater transparency. The top (bottom) panel highlights the magnetic (kinetic) spectrum, with the other shown in the background for reference. The spectra at $tU_{\text{rms}}/L = \tau_w$ (L/U_{rms}) are highlighted in magenta (green). The magnetic (kinetic) spectrum at $t = L/U_{\text{rms}}$ is highlighted with a black solid (dashed) curve. The silver, blue, and green vertical lines indicate the scales of the electron skin depth, the Weibel filaments, and the Larmor radius of particles after dynamo saturation, respectively.

684 itself, in the direction of the field reversal, and in the
 685 cross direction, respectively (Schekochihin et al. 2004).
 686 If the magnetic field possesses a folded structure, its
 687 length, thickness, and width can be represented by
 688 $\ell \sim 1/k_{\parallel}$, $\lambda \sim 1/k_{B \times J}$, and $\xi \sim 1/k_{B \cdot J}$, respectively.
 689 The time evolution of k_{\parallel} , $k_{B \times J}$, and $k_{B \cdot J}$ is shown in
 690 the top panel of Figure 5, together with the domain-
 691 averaged normalized inverse particles' Larmor radius
 692 $(L/2\pi)/\rho_e$. The three wavenumbers initially have large
 693 values set by the Weibel filaments, and drop rapidly
 694 from the beginning of the simulation to $t \approx 0.4L/U_{\text{rms}}$
 695 due to the rapid disentanglement of the helical field
 696 lines by the turbulent flows, visualized in the middle
 697 panel of Figure 5. Starting at $t \approx 0.4L/U_{\text{rms}}$, the
 698 wavenumbers decrease slowly to become nearly con-
 699 stant, with the ordering $k_{\parallel} \approx k_{B \cdot J} \ll k_{B \times J}$, indica-
 700 tive of a folded sheet-like structure. The inverse Larmor
 701 radius $(L/2\pi)/\rho_e$ increases first rapidly up until τ_w
 702 and then slower between τ_w and L/U_{rms} . As the growth
 703 of magnetic energy drastically slows down after L/U_{rms} ,
 704 $(L/2\pi)/\rho_e$ also reaches an approximate saturation. At
 705 $t \approx L/U_{\text{rms}}$, $k_{B \times J} \approx 1/\rho_e$ is observed, suggesting that
 706 the thickness of the folds is comparable to the Larmor
 707 radii of particles. This is consistent with the argument
 708 that the length scale for the magnetic field reversal
 709 cannot become shorter than the local Larmor radius as
 710 a result of the stretching and folding of the flows, as
 711 the field lines are not frozen into the plasma below the
 712 Larmor radius.

3.2.3. Inductive dynamo amplification

713
 714 As the turbulent flows are established and the seed
 715 field becomes coupled to the flow, it becomes possible
 716 for the flows to stretch and fold the magnetic field lines.
 717 The statistical outcome of this process is an inductive
 718 amplification of the magnetic field, known as the plasma
 719 dynamo, which leads to another period of exponential
 720 growth of magnetic energy at $L/U_{\text{rms}} \lesssim t \lesssim 3L/U_{\text{rms}}$
 721 in our simulation, as evidenced in Figure 2. The over-
 722 all growth of magnetic energy can be fit with $\beta^{-1} \propto$
 723 $\exp(0.4U_{\text{rms}}t/L)$, corresponding to a magnetic growth
 724 rate $\gamma \equiv d \ln B / dt \approx 0.2U_{\text{rms}}/L$. This growth rate is
 725 tied to the macroscopic eddy-turn-over rate and is thus
 726 much slower than the rapid growth on the kinetic time
 727 scale during the Weibel stage. The dynamo growth rate
 728 being comparable to the flow-crossing rate suggests that
 729 the inductive amplification is given by the flow on scales
 730 not far removed from the domain scale, and is another
 731 manifestation of the lack of scale separation in our simu-
 732 lation: it is consistent with the fact that, at $t \approx L/U_{\text{rms}}$,
 733 the seed field is so strong that only at scales comparable
 734 to the domain size are bulk flows energetically domi-

670 filament coalescence and rearrangement, the growth of
 671 low- k Weibel modes, and the stretching by the flow. As
 672 a consequence of limited scale separation, when the bulk
 673 flows are well established, the magnetic energy density is
 674 already larger than the kinetic one across a wide range
 675 of scales (at $kL/2\pi \gtrsim 5$). This leaves a narrow range
 676 for the action of plasma dynamo, because the stretching
 677 and folding of magnetic-field lines can only happen at
 678 scales where the flows are energetically dominant.

679 The geometry of the magnetic field can
 680 be characterized using the wavenumbers
 681 $k_{\parallel} \equiv (\langle |\mathbf{B} \cdot \nabla \mathbf{B}|^2 \rangle / \langle B^4 \rangle)^{1/2}$, $k_{B \times J} \equiv$
 682 $(\langle |\mathbf{B} \times \mathbf{J}|^2 \rangle / \langle B^4 \rangle)^{1/2}$, and $k_{B \cdot J} \equiv (\langle |\mathbf{B} \cdot \mathbf{J}|^2 \rangle / \langle B^4 \rangle)^{1/2}$,
 683 which quantify the variation of the magnetic field along

nant (see Figure 4). The strong magnetic field exerts a back reaction on the plasma flow through the Lorentz force, causing the dynamo to start in an already nonlinear regime, skipping the kinematic phase. In this case, although the mirror and firehose instabilities start to grow at $t \approx L/U_{\text{rms}}$ (details explained in the next section), the accelerating dynamo phase described in Section 2.3 cannot be clearly identified in the simulation because the magnetic-field strength at this stage is already too close to its saturated level. Instead, the system transitions directly into Phase IV of Sec. 2.4. As shown in the bottom panel of Figure 2, at larger scales where the strength of the seed field is smaller, the dynamo growth rate at $L/U_{\text{rms}} \lesssim t \lesssim 3L/U_{\text{rms}}$ is higher (e.g., $\gamma \approx 0.7U_{\text{rms}}/L$ for $kL/2\pi = 1$) due to the weaker back reaction of the field on the flow. This leads to a further broadening of the magnetic spectrum and accumulation of energy at the system scale (Figure 4, top panel). The magnetic spectrum at large scales is flatter than $k^{3/2}$ (shown with the black dotted line), which is expected for the kinematic dynamo (Kazantsev 1968). This is consistent with the observation that the dynamo starts in a nonlinear regime. For $t \gtrsim 3L/U_{\text{rms}}$, as the magnetic energy becomes larger and approaches the kinetic energy, the growth of the magnetic field slows down further.

The time evolution of the characteristic wavenumbers and Larmor radius shown in Figure 5 is consistent with the amplification of the magnetic field and the broadening of the magnetic spectrum towards larger scales. As the magnetic field grows in strength, the domain-averaged Larmor radius decreases [$(L/2\pi)/\rho_e$ increases] and becomes smaller than the length scale of the magnetic field in all dimensions. All three wavenumbers slowly decrease, with k_{\parallel} and $k_{B,J}$ approaching $kL/2\pi \approx 2$ to 3 at late times. This suggests the formation of magnetic folds with sizes comparable to the system scale. Such large-scale folded sheets are clearly seen in the right panel of Figure 3.

The dynamo eventually saturates by the end of the simulation when approximate equipartition between kinetic and magnetic energy is reached, $M^2\beta \sim 1$ (Figure 2, top panel). As shown in Figure 4, the peak of the magnetic energy spectrum continues to shift to larger scales until saturation (with the energy density at small k increasing and that at large k decreasing). Although an overall equipartition is reached, the scale-by-scale equipartition does not exist in any scale range of the spectra. The kinetic energy dominates at small k whereas the magnetic energy dominates at large k . Starting from $t \sim L/U_{\text{rms}}$, the local (in k -space) equipartition [$\mathcal{M}(k) \sim \mathcal{K}(k)$] first occurs at around $kL/2\pi \approx 5$

Figure 5: Morphology of the magnetic field. Top: time evolution of characteristic wavenumbers describing the magnetic field and the averaged Larmor radius. The vertical dotted line indicates the time τ_w . Magnetic-field lines at $t = 0.3L/U_{\text{rms}}$ (middle) and at saturation (bottom) are shown. The colored field lines are chosen from regions with strong magnetic field. The grey shaded field lines are randomly sampled through the domain. The color corresponds to the normalized field strength, $|B/B_{\text{rms}}|$.

and then slowly shifts to smaller k . The structure of the turbulence and the energy cascade in this turbulent dynamo remain to be investigated.

3.2.4. Instability-regulated turbulence

In this fully collisionless turbulent dynamo (Phase IV of Sec. 2.4), important parameters such as the viscosity and resistivity are self-consistently determined by the interaction between the plasma and micro-scale fluctuations. The large-scale motions in a collisionless plasma push it out of local thermodynamic equilibrium, and various kinetic instabilities can become unstable due to the developed pressure anisotropy. After the triggered Weibel instability magnetizes the plasma, the Larmor-scale instabilities, namely the mirror and firehose instabilities, become unstable when $|P_{\perp} - P_{\parallel}| \gtrsim B^2/4\pi$.

The presence of these kinetic instabilities in our simulation is indicated in the probability density distribution of P_{\perp}/P_{\parallel} and β_{\parallel} shown in Figure 6. During the Weibel phase, the kinetic-scale filamentary seed field naturally causes a short mean-free-path of the particles, as the largest distance that a particle can travel before pitch-angle scattering is not longer than the length of the Weibel filaments. The scattering off the Weibel seed field confines the pressure anisotropy at small values, i.e., $P_{\perp} \approx P_{\parallel}$ [panel (a)]. The saturated seed field is then organized into folded-sheet structures (at $t \approx L/U_{\text{rms}}$) with coherence scales much larger than the Weibel field. As described in Section 2.4, due to the near conservation of μ , local changes in the magnetic-field strength trigger the mirror and firehose instabilities. The Larmor-scale fluctuations generated by these instabilities start to grow on top of the folded magnetic field and scatter the particles, limiting the growth of pressure anisotropy [panel (b)]. The growing fluctuations eventually become strong enough to pin the pressure anisotropy around the mirror instability's threshold [e.g., at $t = 5L/U_{\text{rms}}$ shown in panel (c)]. Because the strength of the magnetic field is overall growing, $P_{\perp} > P_{\parallel}$ is expected to populate the domain and the mirror instability is dominant. After the saturation of the dynamo, the regions where the field is amplified should balance those where the field is diminished, and therefore, both mirror and firehose instabilities are active, regulating the pressure anisotropy in between their thresholds [panel (d)].

The scattering of particles off the mirror and firehose fluctuations provides an effective collisionality, ν_{eff} , which can be quantified by a pitch-angle scattering rate and measured using the trajectories of tracked particles. One way of quantifying the scattering rate is to study the time evolution of particles' magnetic moments μ , and compute the histogram of the collision time τ_{coll} ,

defined as the time interval for μ of each particle to change by a factor e . The characteristic collision time $\langle\tau_{\text{coll}}\rangle$ is obtained by fitting the histogram with an exponential function (details see Appendix A.3), and is the average time scale on which the conservation of μ is violated. The effective collisionality thus obtained, $\nu_{\text{eff}} = 1/\langle\tau_{\text{coll}}\rangle$, is shown as a function of time in the top panel of Figure 7. In the same panel, the time evolution of $v_{\text{th}}k_{\parallel}/2\pi$ and $3\langle\mathbf{bb}:\nabla\mathbf{u}\rangle/\langle B^2\Delta\rangle$ are shown for comparison. The former quantity represents the scattering rate assuming that the particles' mean free paths are comparable to the length of the magnetic folds, as would be the case for particles either becoming demagnetized at the bends of the folded fields where the field is statistically weaker (Kempski et al. 2023) or scattering off firehose fluctuations that populate these weak-field regions where $\Delta < 0$ locally (St-Onge & Kunz 2018). The latter quantity is based on the assumption that the anisotropy evolves following Eq. (6), which yields a Braginskii-type scattering rate. By $t \simeq L/U_{\text{rms}}$, the folded-sheet structures are formed, the system is magnetized, and the Larmor-scale mirror and firehose fluctuations start to grow. From then on, $1/\langle\tau_{\text{coll}}\rangle$ approaches and, in saturation, matches $\approx 3\langle\mathbf{BB}:\nabla\mathbf{u}\rangle/\langle B^2\Delta\rangle$. With these rates being $\gg v_{\text{th}}k_{\parallel}/2\pi$, this suggests that the collisionality is caused mainly by the particles scattering off micro-instabilities (which regulates the pressure anisotropy) before the particles are able to traverse a fold length. This is consistent with the fact that Δ reaches a steady state at $t \approx L/U_{\text{rms}}$ (Figure 2, top panel).

An effective field-parallel Reynolds number is determined by the effective collisionality $\text{Re}_{\parallel} \equiv U_{\text{rms}}L/(v_{\text{th}}^2/\nu_{\text{eff}})$, and its time evolution is shown in the bottom panel of Figure 7. The Re_{\parallel} first increases at $t < L/U_{\text{rms}}$ as the flows develop, and then decreases until $\text{Re}_{\parallel} \approx 1$. This is consistent with the expectation discussed in Section 2.4 that, as the particle scattering off nonlinear Larmor-scale fluctuations becomes sufficient to regulate the pressure anisotropy, ν_{eff} decreases as the magnetic energy increases. This leads to a decreasing Re_{\parallel} and an increasing parallel viscous scale $\ell_{\nu_{\parallel}}$, which could be the reason for the knee of the kinetic spectrum to shift slightly towards smaller wavenumbers, shown in the bottom panel of Figure 4. The parallel rate of strain of the flow, and hence the dynamo growth rate, are expected to decrease, consistent with the progressively slower growth of magnetic energy before saturation (Figure 2). The detailed scaling dependence of Re_{\parallel} [Eq. (10)], derived under the assumption of Kolmogorov scalings, is not expected to hold in our simulations due to the lack of scale separation and of an inertial range of the turbulence.

Figure 6: Normalized probability density distribution of pressure anisotropy and β_{\parallel} at various moments of time. The solid (dashed) curve represents the threshold for the mirror (firehose) instability.

Figure 7: Top: time evolution of normalized (to $\sqrt{\theta_c}/L$) effective collisionality $\nu_{\text{eff}} = 1/\langle\tau_{\text{coll}}\rangle$ (orange), compared to a parallel streaming frequency $v_{\text{th}}k_{\parallel}/2\pi$ (blue), and a “Braginskii” collision frequency assuming Eq. (6) (green). Bottom: effective parallel Reynolds number implied by ν_{eff} .

4. CONCLUSIONS AND DISCUSSION

In this work we present an analytical theory and a first-principles numerical demonstration of the generation, amplification, and sustenance of magnetic fields under the action of large-scale turbulent flows in a collisionless plasma. In an initially unmagnetized Maxwellian plasma, the developed thermal pressure anisotropy resulting from the phase mixing of large-scale flows triggers the Weibel instability, which depletes the thermal free energy in the pressure anisotropy to produce a filamentary seed magnetic field at plasma-kinetic scales strong enough to magnetize the plasma. After a brief phase of filament coalescence, at around one flow-crossing time, the seed field becomes coupled to the large-scale flows. The turbulent flows start to stretch and fold the magnetic field, producing a field-biased pressure anisotropy via the approximate conservation of the magnetic moments of magnetized particles.

The mirror and firehose instabilities become unstable to this pressure anisotropy and generate Larmor-scale fluctuations. The scattering of particles off of these fluctuations leads to an effective collisionality, which in return regulates the pressure anisotropy, controls the parallel rate of strain of the flow and thus the dynamo growth rate. The magnetic field is inductively amplified until it reaches approximate energy equipartition with the flow. The length scale of the field is found to approach the system scale at saturation, suggesting that a collisionless fluctuation dynamo can produce a magnetic field that is coherent on scales comparable to the turbulence forcing scale. Most importantly, our results provide a proof-of-principle demonstration that equipartition magnetic fields can be produced in an unmagnetized system by large-scale astrophysical flows without resorting to other magnetic seeding mechanisms.

Despite these successes, the predictive ability of our numerical simulations is rather limited. In Section 2, we introduced theoretical arguments and leveraged previous numerical simulations of the plasma dynamo to advance a four-phase evolutionary scenario for the *ab-initio* plasma dynamo (see Figure 1). In this scenario, magnetic fields are self-consistently seeded by the Weibel instability and amplified inductively by random bulk flows in a plasma whose viscosity is ultimately controlled by rapidly growing, microscale, mirror and firehose instabilities and therefore dependent upon the plasma β . Some features of this scenario are borne out by our numerical simulations, but several others cannot be tested at this time because of the very large scale separation they require (namely, $L/d_i \gtrsim 10^5$, if not larger). In our simulation with $L/d_e = 378$, processes such as the decrease of β^{-1} during the predicted reconnection-controlled coalescence of the Weibel seed field and the kinematic (and potentially explosive) phase of the dynamo cannot be unambiguously identified. Because of the limited L/d_e , the length scale for the Weibel fields and the effective parallel viscous scale $\ell_{\nu\parallel}$ are not well separated from the domain scale. Therefore, future studies are required

to test the tentative conclusion that, in the collisionless plasma dynamo, the coherence scale of the saturated magnetic field is close to the forcing scale and that the Weibel-generated fields at plasma kinetic scales can transition into astrophysical scales.

Another unconstrained piece of physics concerns what sets the characteristic reversal scale of the amplified magnetic field, particularly during the “kinematic” linear phase in which the back reaction of the magnetic field on the flow (through the Lorentz force) is negligible and the magnetic energy resides at the smallest available scale. In the kinematic phase of the $\text{Pm} \geq 1$ MHD dynamo, this scale is the resistive scale (Kazantsev 1968; Kulsrud & Anderson 1992; Schekochihin et al. 2002; Galishnikova et al. 2022). In a collisionless dynamo, it is reasonable to expect this scale to instead be comparable to (or at least related to) ρ_e , the scale below which the magnetic field is not “frozen” into the plasma and the flow cannot efficiently stretch and amplify the magnetic field. If true, then $1/k_{J \times B} \sim \rho_e \propto B^{-1}$ during the linear phase of the dynamo; as the magnetic field is amplified, the characteristic reversal scale of the field would then continuously shrink. This would be a unique feature of a fully kinetic dynamo. In an electron-proton plasma, the expectation for the reversal scale is less clear. The above argument would continue to hold for ρ_e ; we cannot think of any fundamental reason why the reversal scale could not be below the proton Larmor scale. Indeed, in the hybrid-PIC simulations performed by St-Onge & Kunz (2018), in which the explicit resistivity is a (constant) input parameter, there are stages of the dynamo in which $k_{J \times B} \rho_i > 1$. Those authors argued that, in this case, the protons would undergo Bohm-type diffusion, rather than scatter off of the mirror (firehose) fluctuations located within (at the ends of) the folds. Dynamo simulations with $m_i/m_e \gg 1$, though too computationally expensive at this time, could test this idea.

The demonstrated self-consistent generation of near-equipartition magnetic fields under the action of large-scale turbulent flows has important implications for the origin of intracluster fields. The energy density of a $\sim \mu\text{G}$ magnetic field in the ICM is usually comparable to that of the turbulent motions; for example, the energy density of a $10 \mu\text{G}$ magnetic field approximately matches the kinetic energy density of a hydrogenic plasma with velocity dispersion $\approx 164 \text{ km s}^{-1}$ at a number density $\approx 0.02 \text{ cm}^{-3}$, parameters measured in the ICM of Perseus (Collaboration 2016). This suggests that astrophysical turbulence may itself explain the observed $\sim 1\text{--}10 \mu\text{G}$ intracluster fields (Kunz et al. 2022). Future numerical studies that achieve asymptotically large scale separation, or perhaps reduced models

adopting accurate microphysical closures, are needed to further test this statement.

Finally, we note that other important and often-advocated origins of cosmic seed magnetic fields are not considered in this work. One idea is that very weak seed fields are generated by various fluid or plasma-kinetic instabilities—e.g., the Biermann (1950) and/or Durrive & Langer (2015) batteries—during large-scale structure formation in the early Universe in cosmological accretion shocks, (re-)ionization fronts, and/or cosmological linear over-densities (Pudritz & Silk 1989; Subramanian et al. 1994; Kulsrud et al. 1997; Ryu et al. 1998; Gnedin et al. 2000; Naoz & Narayan 2013). The resulting large-scale seed fields have strengths $\sim 10^{-25}\text{--}10^{-18} \text{ G}$, which are then supposedly amplified to dynamical strengths through gravitational collapse and/or stellar evolution within galaxies, and subsequently injected into and diluted throughout the intergalactic medium by powerful galactic winds or jets (Rees & Setti 1968; Rees 1987; Furlanetto & Loeb 2001). The conjecture of a such proto-galactic origin is supported indirectly by observations of early enrichment of galaxy clusters by metals (Mantz et al. 2020), namely, *XMM-Newton* observations of a cluster at redshift $z \simeq 1.7$ with high metal enrichment ($\sim 1/3$ Solar). If such galactic pollutants were accompanied by $\sim \mu\text{G}$ galactic magnetic fields, it is possible that the seed fields in the ICM have a proto-galactic origin. However, the feasibility of this seeding mechanism depends upon the efficiency with which such fields are dispersed and diluted throughout a turbulent, weakly collisional ICM, a process that remains to be studied in detail. These mechanisms, as well as other more exotic cosmological origins of primordial seed fields, are reviewed by Durrer & Neronov (2013), Subramanian (2016), and Brandenburg & Ntormousi (2023, §5). Our paper explores the scenario that magnetic fields can be originated from the gravitationally driven macroscopic flows in the ICM without relying on assumptions about proto-galactic magnetic fields. However, it is important to note that the various conjectured origins of magnetic fields are not mutually exclusive, and future studies are required to distinguish their respective contributions to the production of intracluster magnetic fields.

In the final stage of this work, we became aware of a similar paper presenting results from an independent PIC simulation study of Weibel-seeded fluctuation dynamo in a pair plasma (Sironi et al. 2023). In areas of overlap between our results and theirs, we find agreement.

APPENDIX

A. DETAILS OF NUMERICS.

A.1. *External forcing*

In our simulations, an external mechanical body force, $\mathbf{F}_{\text{ext}}(\mathbf{x}, t) = F_{\text{ext},x}(\mathbf{x}, t)\hat{\mathbf{x}} + F_{\text{ext},y}(\mathbf{x}, t)\hat{\mathbf{y}} + F_{\text{ext},z}(\mathbf{x}, t)\hat{\mathbf{z}}$, is applied to particles to drive large-scale bulk flows. The forcing is composed of a superposition of sinusoidal modes in space, having six solenoidal (shearing) modes at the box scale, with wavevectors $\mathbf{k}L/2\pi \in \{(0, 1, 0), (0, 0, 1)\}$ for $F_{\text{ext},x}$, $\mathbf{k}L/2\pi \in \{(1, 0, 0), (0, 0, 1)\}$ for $F_{\text{ext},y}$, and $\mathbf{k}L/2\pi \in \{(0, 1, 0), (1, 0, 0)\}$ for $F_{\text{ext},z}$. The amplitude for each mode of the force is chosen to be $T_{e0}/(\sqrt{6}L)$. Although the force is correlated at the large scale, it has a random phase at each value of \mathbf{k} that is evolved independently following the Langevin equation in TenBarge et al. (2014). To obtain a low Mach number flow, we choose a very low driving frequency ω_0 and decorrelation rate γ_0 relative to the thermal timescale; specifically, $\omega_0 = 0.03v_{\text{th}}/(L/2\pi)$ and $\gamma_0 = 0.83\omega_0$.

A.2. *Inverse Compton (IC) radiation*

In order to achieve a steady temperature, external IC radiative cooling is included in the simulations. The emission process of IC radiation (in the optically thin limit) exerts a radiation backreaction force

$$\mathbf{F}_{\text{IC}} = -\frac{4}{3}\sigma_{\text{T}}U_{\text{ph}}\gamma^2\mathbf{v}/c \quad (\text{S1})$$

to electrons and positrons Landau & Lifshitz (1975). Here $\sigma_{\text{T}} = (8\pi/3)(e^2/m_e c^2)^2$ is the Thomson cross-section, U_{ph} is the energy density of the ambient photon field (with the photon density assumed to be isotropic), and $\gamma = (1 - v^2/c^2)^{-1/2}$ is the particle Lorentz factor. In contrast to synchrotron cooling, which drives pressure anisotropy of the plasma by reducing the field-perpendicular component of the plasma pressure (Zhdankin et al. 2023), the IC cooling is isotropic and mainly radiates at the high-energy tails of the plasma distribution. Therefore, the IC cooling is not expected to affect the dynamics of the mirror and firehose instabilities, or the properties of the plasma dynamo.

A.3. *Measurements of effective collisionality*

The effective collisionality presented in the numerical results (in Figure 7) is quantified by the pitch-angle scattering rate and measured by studying the time evolution of magnetic moments μ of 10^4 tracked particles. We first divide the entire evolution into 20 time intervals. In each time interval, we look at the time evolution of μ for each tracked particle, compute the collision time τ_{coll} required for μ to change by a factor of e , and record the particle's gyro-radius ρ_e averaged over all the time steps within the time interval τ_{coll} . We then divide the ensemble of τ_{coll} into three groups based on the associated ρ_e ($\rho_e \geq L/2$, $L/30 < \rho_e < L/2$, and $\rho_e \leq L/30$), and compute the histogram of τ_{coll} for each group.

An example histogram for the time interval $6.33 < tU_{\text{rms}}/L < 6.58$ is shown in Figure S1. The τ_{coll} of particles from the unmagnetized group $\rho_e \geq L/2$ cannot be used to calculate the scattering rate, because μ is not an adiabatic invariant for unmagnetized particles. The histogram of the group $L/30 < \rho_e < L/2$ is similar to that of the well-magnetized group $\rho_e \leq L/30$, suggesting that the particles are sufficiently magnetized to study the statistics of τ_{coll} . The characteristic collision time $\langle \tau_{\text{coll}} \rangle$ is obtained by fitting the histogram with an exponential function, $\exp[-\tau_{\text{coll}}/\langle \tau_{\text{coll}} \rangle]$, while the range $\tau_{\text{coll}}V_{\text{th}}/L < 0.2$ is not taken into account for the fitting to exclude the change of μ due to Bohm-like diffusion (i.e., particles sampling multiple field reversals during their gyromotion). The effective collisionality for each time interval is then evaluated as $\nu_{\text{eff}} \equiv 1/\langle \tau_{\text{coll}} \rangle$.

B. PARAMETER SCAN OF L/D_E

As a supplement to the main text, we present two group of runs with varying scale separation. The first group has $M \simeq 0.3$ at steady state and $L/d_e \in \{126, 189, 252, 378\}$, as well as one run with uncharged particles (of which L/d_e is an irrelevant parameter because d_e has no physical meaning). The second group has $M \simeq 0.1$ and $L/d_e \in \{48, 64, 96, 126, 189, 252\}$. The time evolution of M^2 and β^{-1} for the first (second) group is shown in Figure S2 (Figure S3).

Figure S1: An example histogram of collision time τ_{coll} of tracked particles, grouped according to their ρ_e/L , during the time interval $6.33 < tU_{\text{rms}}/L < 6.58$.

Figure S2: Time evolution of M^2 (top panel) and β^{-1} (bottom panel) for runs with varying $L/d_e \in \{63, 126, 189, 252, 378\}$ and steady-state Mach number $M \approx 0.3$. The run with $L/d_e = 63$ uses uncharged particles.

1254 The run with uncharged particles provides a benchmark for the effects of magnetic fields. As the system is contin-
 1255 uously driven by the external force, the β^{-1} stays at the level of numerical noise. The M^2 increases slowly and is of
 1256 a much smaller value than other runs, consistent with the argument that an unmagnetized plasma (or the neutral gas
 1257 here) is subject to efficient phase mixing, and thus is effectively viscous.

1258 The time evolution of M^2 differs for systems with varying L/d_e . Within each group, although the values of M^2 at
 1259 the steady state are similar, runs with larger L/d_e have a faster acceleration of the flow in the beginning and shoot
 1260 to a higher value of M^2 before decreasing to the steady value. This is consistent with the argument made in the
 1261 main text that during the initial Weibel phase, the effective collisionality is determined by the particle scattering at
 1262 the ends of the Weibel filaments. With larger L/d_e , the Weibel filaments have smaller length scales [compared to the](#)
 1263 [system size](#) in each dimension [$k_w L \sim (L/d_e)^{3/4} M^{1/8}$, equivalent to Eq. (2)], which lead to a shorter mean free path
 1264 of the particles, i.e., larger effective collisionality or smaller viscosity for the system, and thus a faster acceleration and
 1265 higher peak M for the flows. However, it seems unlikely that this trend will continue to values of $M > 1$, when the
 1266 flow becomes supersonic.

1267 Systems with varying L/d_e (for $L/d_e \gtrsim 100$) show similar evolution of β^{-1} (Figure S2, bottom panel). The levels
 1268 of β^{-1} given by the Weibel seed fields have a weak dependence on L/d_e , as expected given Eq. (1). The subsequent

Figure S3: Time evolution of M^2 (top panel) and β^{-1} (bottom panel) for runs with varying $L/d_e \in \{48, 64, 96, 126, 189, 252\}$ and steady-state Mach number $M \approx 0.1$.

1269 plasma dynamo amplifies the magnetic fields with a growth rate that is similar for all these runs. This is consistent
 1270 with the fact that even for the run with the largest L/d_e ($=378$), which is analyzed in the main text, the parallel rate
 1271 of strain is mainly given by flows at the forcing scale. The dynamo growth rate (for runs with $L/d_e \leq 378$) is tied to
 1272 the flow-crossing rate (at the forcing scale), independent of L/d_e . The effective collisionality is expected to be caused
 1273 by particle scattering off the Weibel filaments in the Weibel phase, and by the particle scattering off the mirror and
 1274 firehose fluctuations in the dynamo phase. The dependence of the collisionality on L/d_e during these two phases are
 1275 different, which leads to the results that the effective collisionality (viscosity) is larger (smaller) with larger L/d_e in
 1276 the early Weibel phase, but does not have a strong dependence on L/d_e during the dynamo phase.

1277 For the run with $L/d_e = 48$ (Figure S3, bottom panel), it is unclear whether a dynamo phase exists after the Weibel
 1278 stage. This could be due to the significant electron Landau damping of the magnetic fields under the very limited scale
 1279 separation. This suppression of dynamo at small system sizes is consistent with the previous study demonstrating the
 1280 role of electron Landau damping in inhibiting dynamo (Pusztai et al. 2020).
